**Abstract:**

Recent work on structure building and mapping in Minimalist syntax makes explicit reference to *workspaces*; however, it is still an underexplored area. This paper is an attempt to (a) analyse the notion of 'workspace' as used in current Minimalist syntax and (b) provide a definition of 'syntactic workspace' that can help us capture interesting empirical phenomena. In doing this, we confront set-theoretic and graph-theoretic approaches to syntactic structure in terms of the operations that can affect syntactic objects and how their properties are related to the definition of workspace. We analyse the consequences of conceptualising 'syntax' as a set of operations that affect local regions of the workspace, defining directed graphs.

**Keywords:** Syntax; workspace; phrase markers; copy; topological space; graph theory

## 1. Introduction: setting the scene

A recurrent topic in generative grammar has been the need to hold on to structure, either because it needs to be kept within probing memory for further operations or because an object has been subjected to a reordering rule, as in (1a-b) (where strikethrough indicates unpronounced but syntactically active material):

- 1) a. Mary<sub>i</sub> thinks [that Peter likes [an old picture of herself<sub>i</sub>]]  
b. [Which picture of herself] does [Mary think [that Peter likes ~~which picture of herself~~]]?

The non-local dependencies in (1), one base-generated co-indexing and the other a product of movement, illustrate the necessity of maintaining structure active and syntactic objects accessible for non-subsequent derivational steps. Operations that refer to non-subsequent derivational steps, or to chunks of structure, require syntactic objects of variable complexity to be *stored* somewhere, where they can be accessed and retrieved. In connection to this, recent generative theory has appealed to the idea of *workspaces*, and it is playing an increasingly important role in the definition of Merge, Agree, and Minimal Search (e.g., Chomsky 2019, 2020a, b, 2021; Chomsky et al. 2019; Collins and Stabler 2016; Epstein et al. 2020; Jayaseelan 2017; Kato et al. 2016; Kitahara 2021; Komachi et al. 2019; Müller 2004: 298; Reuland 2011: 20; Milway 2022). A careful look at the properties of workspaces and how they determine conditions on allowable structures and relations is thus essential to advance Minimalist inquiry. In this paper we propose a topological theory of workspaces, and explore some of its architectural and empirical consequences.

Let us further illustrate the kind of problem that requires reference to derivational spaces. Assume that we have objects X and Y in a local relation, as represented in the unordered set (2):

- 2) Merge(X, Y) = {X, Y} (e.g., {die, John})

Now suppose that there is some relation *R* between X and Y: for instance, X theta-marks Y. That relation needs to be maintained throughout the derivation, or reconstructed at the level of semantic interpretation if disrupted by a reordering operation. Let us now introduce a further element in the

derivation, W, which requires a local relation with Y to satisfy some requirement (which one in particular is not relevant for the present argument). W is external to {X, Y}:

- 3)        {W, {X, Y}} (e.g., {T, {die, John}})

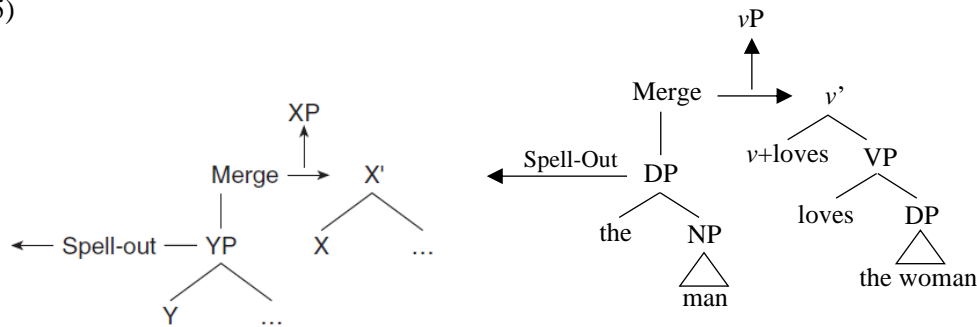

What happens if a local configuration between W and Y is required which excludes X? A movement approach under set-theoretic assumptions can either (a) move Y to a higher position in the checking domain of W, outside the scope of X leaving a co-indexed trace behind (the so-called *trace theory*), or (b) copy Y and re-introduce Y in the derivation (the *Copy Theory of Movement*, Chomsky 2000; Nunes, 2004; Uriagereka 2002 and much related work). Both options are diagrammed below:

- 4)        a. {Y<sub>i</sub>, {W, {X, t<sub>i</sub>}}}  
          b. {Y, {W, {X, Y}}} (e.g., {John, {T, {die, John}}})

In both cases, the structure is extended by means of new symbols: in (4a), we add a *trace* of Y, an index to Y and *t*, and expand the structure; in (4b) we add a copy of Y and similarly expand the structure. In both cases there is a local relation between W and Y, as required, but at the cost of introducing additional terms (a trace or a copy). Moreover, the very idea of copying requires not only an operation that takes Y and somehow produces another Y (Chomsky 2020a: 44), but this must happen *somewhere*, where the copy is stored and where it can be retrieved from: this ‘somewhere’ has usually been referred to as a *workspace*.

Consider, alternatively, the case of Merging two complex syntactic objects: when Merge applies to {XP, YP}, parallel workspaces where each of these objects is derived independently from the other are invoked. Uriagereka (2002) applies this approach to the derivation of complex specifiers under Multiple Spell-Out: a phrasal specifier is a unit within which asymmetric c-command relations can be defined unambiguously (a ‘command unit’), and must be Spelled-Out separately from the derivational current to which it attaches (see also Jayaseelan 2017: 121, fn. 10, who needs parallel workspaces even for arguments, if phrasal):

5)

Nunes (2004) and Milway (2022) multiply workspaces in their analyses of adjunction, with Nunes (2004: 139) defining sideways movement in parasitic gaps as movement ‘from a “subordinated” to a “subordinating” derivational space’. To summarise, an explicit workout of the concept of *workspace* seems unavoidable, yet there are few explicit characterisations of what *workspaces* are, how they interact with the generative procedure in Minimalist syntax, and, most importantly, how properties of operations and objects are related to (or depend on) properties of the workspace.

The paper is structured as follows: after a brief literature review in **Sections 1.1** and **1.2**, **Section 2** defines topological spaces and explores how we can use topological characterisations of spaces to our advantage in syntactic theory. In addition to providing a general definition of topological space, we argue for a specific technical implementation of workspace-based syntax, through a graph-theoretic lexicalised grammar. **Section 3** compares two kinds of topological spaces (ultrametric and metric) as models for syntactic workspaces, and argues that derivations may be conceptualised as mapping one to the other, locally: syntactic relations change the topological properties of the workspace. Some empirical consequences of this view are explored in **Section 4**.

### 1.1 Workspaces in the Minimalist literature: questions and problems

The generative procedure in Minimalist syntax takes the form of an operation of ‘unordered binary set formation’ (Chomsky 2019, 2020a: 22, 2021; Collins 2017; Epstein et al. 2015a, b; Kitahara 2020, 2021):  $\text{Merge}(X, Y) = \{X, Y\}$ . Recently, Merge has been recast as MERGE, giving workspaces a central role. Chomsky et al. (2019: 236, 245) say:

‘MERGE operates over syntactic objects placed in a workspace: the MERGE-mates X and Y are either taken from the lexicon or were assembled previously within the same workspace’

‘All syntactic objects in the lexicon and in the workspace WS are accessible to MERGE; there is no need for a SELECT operation [...]. WS represents the stage of the derivation at any given point.’

where MERGE is defined as follows (Chomsky 2020a: 34, 42; 2021: 20; Komachi et al. 2019: 275):

‘MERGE(P, Q, WS) = [{P, Q}, X<sub>1</sub>, ..., X<sub>n</sub>] = WS’, where if Y is a term of WS, it is a term of WS’.

A derivation, then, is a sequence of workspaces <WS<sub>1</sub>, WS<sub>2</sub>, ..., WS<sub>n</sub>> where WS<sub>n</sub> is the result of MERGE(WS<sub>n-1</sub>). In this context, an important question arises: does the stage of the derivation at any given point include all objects in the lexicon<sup>1</sup>? In this respect, Chomsky (2021: 16) claims that

‘At each stage of the derivation, *we have a set of already generated items that are available for carrying the derivation forward (along with LEX, which is always available). Call this set the Workspace WS. WS determines the current state of the derivation. Derivations are Markovian. The next step doesn’t have access to the history, but [...] WS includes everything previously generated.*’ [highlighting ours]

Chomsky here clearly separates WS from LEX: syntactic computation involves *two* distinct spaces, such that lexical elements are taken from LEX and combined in WS. This begs the question of how a derivation would begin: in the definition of MERGE(P, Q, WS) (e.g., Chomsky 2020a: 48; Kitahara 2021; Komachi et al. 2019: 275), how are P and Q selected, considering that Chomsky et al. (2019:

---

<sup>1</sup> The answer is *yes* in Kato et al. (2016: 35): “We assume that WS is the set consisting of SOs already constructed and LIs in the Lexicon, that is,  $WS = \{\Sigma_1, \dots, \Sigma_n\} \cup \text{Lexicon} = \{\Sigma_1, \dots, \Sigma_n, LI_1, \dots, LI_m\}$ ”. Also in Chomsky (2020a: 45): “for a given I-language, the set of workspaces—the set notice, not the least set—is the set containing the lexicon and containing MERGE (P, Q, WS) for any P, Q and WS that has already been generated” (our highlighting); also (2020a: 56). Chomsky (2020b) defines the workspace as “the set of objects that are available for further computation [...] the workspace specifies the current state of computation”; in this sense, the workspace is analogous to Turing’s (1936: 231) definition of ‘configuration’. If External Merge involves access to the lexicon, then elements in the lexicon must be available for further computation (since there is no Select operation, and therefore no Lexical Array), thus belonging to the workspace.

245) reject the existence of an operation SELECT (but see Chomsky 2021: 36)? The only thing that is specified is that P and Q are accessible in the workspace, which does not answer this particular question if LEX and WS are disjoint spaces. Accessibility also requires a special stipulation, in that either only a subset of LEX is ‘accessible’ (possibly through a lexical array or numeration, the selection of which remains mysterious) or all of LEX is. We will see that one of the advantages of our proposal is that it allows us to maintain the idea that LEX is always available, without multiplying the spaces.

The absence of detailed discussion about the nature and properties of the workspace and its relation to LEX is also concerning because the properties of the workspace may impose conditions on the operations that can apply and the dependencies that may hold: the very notions of *local* and *non-local* dependency need to be reconceptualised in terms of what is accessible at each derivational step<sup>2</sup>. For definitions, Chomsky et al. (2019: 236) refer the reader to Collins and Stabler (2016: 46), who say:

**‘Definition 10.** A stage (of a derivation) is a pair  $S = \langle LA, W \rangle$ , where LA is a lexical array and *W* is a set of syntactic objects. In any such stage *S*, we will call *W* the workspace of *S*. [...] by convention we will reserve the term “syntactic object” for those elements built up in the course of the derivation and contained in the workspace.’ [highlighting ours]

In this context we can consider Chomsky’s view alongside Collins and Stabler’s, as they represent what can be found elsewhere in the literature (e.g., Collins 2017: 63; Milway 2022; Müller 2004: 298).

Several questions arise. If the workspace of a derivation is the structure already built, then how does it help in formulating a theory of copies (vs. repetitions)? Do properties of the workspace play

---

<sup>2</sup> In Chomsky’s recent works (e.g. 2020c) phases are maintained as entities in the theory but defined in terms of designated ‘endmarkers’ for structural probing within sets:  $v^*$  and C. Crucially, in that approach locality is not defined in terms of properties of the workspace.

any role in defining locality relations? In sum: what exactly does proposing the existence of a workspace buy us in theoretical and empirical terms under current Minimalist assumptions?

## 1.2 Copies and workspaces

Let us briefly focus on copying. Suppose that the workspace is the lexical array + the syntactic object being built. This does not help in solving the issue of determining ‘where copies are stored temporarily’ or, indeed, what copies are. Consider the following derivation (Chomsky 2020a: 48):

- 6) a.  $\{b\}$
- b.  $\{a, b\}$
- c.  $\{b_1, \{a, b_2\}\}$

In (6),  $b_1$  is a copy of  $b_2$ , IM to the set  $\{a, b\}$ . As Gärtner (2022) observes, in order to avoid issues with the set-theoretic axiom of extensionality and represent the intended use of copies in syntax, (6c) needs to either be formalised as a multiset (a collection which allows for multiple instances of an element which would otherwise be counted only once, by the axiom of extensionality) or include diacritics (such that  $b_1$  and  $b_2$  are ‘copies’ in name only): if IM ‘produced’ two copies of  $b$  (the wording is Chomsky’s 2020a: 44; Chomsky 2021: 16 proposes an operation FORMCOPY which - informally- annotates distinct elements of a set with the relation *copy-of*), then (6c) would contain two distinct objects assigned to the indexed category  $b$ . Chomsky et al. (2019: 237) offer no set-theoretic basis for their claim that in an object like (6c) there is a ‘discontinuous’ [sic] object  $b$ . Where are copies produced and stored? How is the object containing  $b_1$  and  $b_2$  interpreted? How many spaces do we need to make this system work?

As observed above, the Copy-based approach has some problems pertaining to the lack of explicitness about the specific mechanisms involved in copying syntactic objects and linking them such that in (6c) there would somehow be only one ‘discontinuous’ object and not two distinct ones. Stroik and Putnam (2013: 20) formulate the issue clearly (cf. Jayaseelan 2017: 115-116):

‘To “copy X” is not merely a single act of making a facsimile. It is actually a complex three-part act: it involves (i) making a facsimile of X, (ii) leaving X in its original domain D1, and

(iii) placing the facsimile in a new domain D2. So, [...] to make a copy of a computer file, one must reproduce the file somewhere in the computer (at least in temporary memory).’

It is important to point out that the problem of specifying *where* operations take place arises for both EM and IM. Stroik and Putnam (2013: 21) propose that the distinction between EM and IM can be rethought within a ‘Copy-only’ system in which differences are determined by the source and the goal of the *Copy* operation (EM would be ‘Copy from lexicon-to-phrase marker’, and IM ‘Copy from phrase marker-to-phrase marker’): this reworking of IM and EM makes it explicit that they differ in terms of the *spaces* that get accessed in each case and how the targeted syntactic object is affected – whether the space gets extended or not- (cf. Stroik, 2009). Current Minimalism adopts a different perspective. Chomsky (2020a: 23) claims that EM is more complex than IM in that it involves a relation between two distinct spaces, and possibly a further operation ‘Select’ such that only some elements of LEX are used in any given derivation (e.g., Chomsky 2000: 101, 2012: 3; but see Chomsky et al. 2019: 245)<sup>3</sup>. This is a direct and (so far as we can see) unavoidable consequence of dissociating *lexicon* from *syntax* and these two from the sound and meaning systems. And it is one of the issues that a theory of workspaces should address.

In the sections that follow we make a concrete claim: the syntactic workspace will be defined as a *topological space*, and syntactic objects are either (i) points in the workspace or (ii) graphs whose nodes are points in the workspace. In a departure from set-theoretic syntax, we will argue that syntactic operations relate expressions in the workspace by delivering directed graphs: anticipating discussion from **Section 2.1**,  $\text{Merge}(X, Y) = \{X, Y\}$  will be replaced by  $\text{Merge}(X, Y) = e\langle X, Y \rangle$  (a directed edge from X to Y, capitalising on the asymmetry of Merge in the original definitions), where

---

<sup>3</sup> Blümel (2017: 15) makes a curious argument against multidominance related to this point:

‘[having External Merge deliver Multidominance] means that a verb like *loves* introduced into the derivation is simultaneously part of the lexicon and part of the derivation, i.e. it is “multiply dominated” in a structure of the current derivation and by the lexicon – clearly, an absurd result.’

This argument relies on the strange idea (never actually put forth by anyone so far as we know) that dominance is a relation that holds between elements in the lexicon and the usual assumption that the lexicon and the workspace are disjoint. The conclusion that Blümel wants to avoid, and which requires the introduction of an asymmetry between Internal and External Merge, is only reached under a view where the lexicon works like a phrase marker.

X and Y are points in the workspace corresponding to basic expressions of the language indexed by a set of uniquely identifying addresses.

We are primarily concerned with two aspects in the analysis of syntactic dependencies: (i) the relevance of the notion of distance between any X and Y in the definition of syntactic dependencies, and (ii) the properties of the spaces where these dependencies are defined and how they constrain allowable relations: how we can make properties of structural descriptions fall out from properties of the workspace. We will focus on a topological interpretation of the notion of distance between elements in that space that we can use to shed new light on the problem of syntactic dependencies assuming, along Minimalist lines, that syntactic operations (in particular, Copy and Re-Merge, but also indexing and the determination of structural contexts for occurrences of syntactic objects) occur somewhere. We depart from current Minimalism in the characterisation of the operations themselves and the objects generated by these operations, and argue that this departure results in simplifications for the theory of syntactic dependencies (and the *de facto* elimination of copies). In addition to providing an explicit definition of *workspace* and analysing the consequences of adopting it, the main innovation of our work consists of the proposal that computational operations affect the workspace itself rather than operating over objects ‘contained’ in the workspace.

## **2. Basic properties of spaces**

If we want the notion of workspace to work for us, theoretically and empirically, we need to provide an explicit characterisation of what a workspace is, what properties it has, and how it determines the kinds of operations that can apply in it and the properties of objects that are inputs and outputs of those operations. To fully understand what assuming workspaces in syntax commit us to, some definitions are in order: as anticipated above, we will explore the possibility that syntactic workspaces are topological spaces, primarily because this would make available to us a set of mathematical tools that we can use in our inquiry. This approach implies a departure from the literature reviewed in the previous section; we will argue that it is justified in that solves or avoids the problems and ambiguities identified above.

First, then, we need to introduce the concept of *topological space* (see Sutherland, 2009: Chapter 5 for basic notational and terminological points). A topological space is defined as a set of points, along with a set of neighbourhoods for each point, which satisfy a set of axioms relating points and neighbourhoods. This is a very general definition, so we must provide further details.

Let  $A$  and  $B$  be points in a topological space  $X$ . Then, we need to define the *neighbourhoods* of  $A$  and  $B$ , call them  $U(A)$  and  $U(B)$ . If  $A$  is a point in  $X$ , the neighbourhood of  $A$  is a subset  $U$  of  $X$  that includes an open set  $V$  containing  $A$  (Reid and Szendroi 2005: 108). In other words, the neighbourhood of  $A$  in  $X$  is a set properly containing  $A$  where one can move some amount without leaving the set: there exists a non-zero number  $\varepsilon$  such that one is in the neighbourhood of  $A$  if one's distance to  $A$  is equal to or smaller than  $\varepsilon$ . If we now consider distinct points  $A$  and  $B$  in  $X$ , we can now define conditions pertaining to the relation between  $U(A)$  and  $U(B)$ , which will define different kinds of topological spaces. A set is *open* iff it is a neighbourhood for every one of its points, and *closed* otherwise (if there is a boundary set, then the union of an open set and its boundary set defines a closed set). The distinction between closed and open neighbourhoods is essential, since bringing points closer together (thus affecting the *distance* function between them) can make their neighbourhoods intersect if these are open<sup>4</sup>. We can provide a graphical representation of disjoint closed neighbourhoods for  $A$  and  $B$  in a topological space  $X$ :

7)

The notions of open and closed neighbourhoods should resonate with the syntactician.

Consider a tree diagram like (8):

---

<sup>4</sup> We can choose between different axioms which relate points and their neighbourhoods, and the specific axioms that we choose gives us a classification of spaces. Furthermore, we can define functions that take us from one kind of space to another: the possibility to transition from one kind of space to another will become relevant below (for technical details, Hazewinkel 2001; Willard 2004).

8)

In X-bar syntax, X ‘projects’ an XP, an object whose distribution and semantic interpretation are determined by the properties of X, the ‘head’ of the phrase. As has been observed repeatedly in the literature there are problematic issues with the idea of ‘intermediate’ and ‘maximal’ projections that have motivated a departure from the XP-X’-X template used in X-bar theory and the adoption of so-called bare phrase structure (BPS) under Merge: essentially, trees without extrinsic labels (like NP, VP, etc.), bar levels, or unary-branching. Under BPS assumptions, (9a) becomes (9b) (e.g., Chomsky 1995a: 63-64, 1995b: 226-228):

Note that in (9b) we can use ‘VP’ as a shorthand for the set  $\{saw, \{saw, John\}\}$ , a ‘proxy’ for a set, as it were (as in Seely 2015: 124). It is, however, no longer a part of the syntactic representation strictly speaking (Chomsky 1995b: 247).

If we adopt the idea that syntactic workspaces are topological spaces (and thus that phrase markers are topological graphs), we can ask what it means for XP to be the ‘projection’ of X from a different perspective which allows us to simplify the theoretical machinery and, as we will see in **Section 2.2**, has independent empirical advantages: using the definitions provided above, the ‘projection’ of a head H (specifically, its c-projection) can be characterised in terms of relations in the workspace as the neighbourhood of H. In other words: for X, Y, and W points in the workspace, the neighbourhood of

X in (7) contains WP and YP (which in turn are the neighbourhoods of W and Y respectively). Crucially, the syntactic objects that belong to the neighbourhood of a head are selected by that head: we advance the claim that neighbourhoods are units of argument structure, in that selectional properties of this head are satisfied within neighbourhoods (see also Frank 2002: 55, 2013: 240; Hale and Keyser 2005: 11). (10) is a first approximation to what such a simplification of phrase structure would deliver:

Here, XP and YP are the neighbours of X. In classical X-bar trees WP is not directly a neighbour of X, but it is the neighbour of a node labelled XP: it is further away from X than YP, but still within the open neighbourhood of X. What we call XP in BPS, then, is a segment of the category X which acts as a boundary for the neighbourhood of X. A ‘head’, in this view, must be directly connected to all its dependant nodes: in BPS something along these lines is accomplished with multi-segment categories (as in (8b)), but these segments are category tokens, not category types. This initial simplification of phrase structure allows for the elimination of intermediate projections (on the syntactic inertness of which see e.g. Chomsky 1995a; Collins 2002; Hornstein and Nunes 2008; Seely 2015) without additional stipulations. Pursuing this idea will entail a departure from the set-theoretic foundations of current Minimalist syntax.

We can push this idea further. The core of it is that syntactic operations create local neighbourhoods in the workspace. We can now recast (8) in different terms. Let WS be our workspace, with X, Y, and W points in WS. Then, the syntactic object we called XP is not a segment or a category, but a subset of WS (since every point in XP belongs to WS). YP is an *interior set* of XP, and WP is a *boundary set*: their union is the closure of the set XP. That is: W and its neighbourhood, and Y and its neighbourhood, are subsets of XP: we will see that Y and W differ in terms of how their neighbourhoods are derivationally connected to X’s and whether they are

accessible for probing from outside XP. This allows us to make the notion of ‘projection of X’ (and the definition of the building blocks of syntax) into a concept that, configurationally, does not need independent definitions other than ‘point’ and ‘neighbourhood’, which we need to define *workspace* anyway. This is a desirable consequence of the present view, as properties of local derivational units can now be defined in terms of the workspace.

## 2.1 Two substantive commitments

The approach to workspaces adopted here is compatible with different ways to define the atomic units of syntax (adopted by different theories): lexical items, features, constructions, signs, roots and functional morphemes, or basic expressions. A space is a set of points and a metric defined on them; there are no formal constraints on what ‘points’ correspond to delivered by the formalism: they are provided by a linguistic theory and the choice, so far as we can see, is eminently empirical. However, a choice must be made to apply the formalism. In the present view, points in the workspace are *basic expressions* of the language (Oehrle et al. 1988; Schmerling 2018)<sup>5</sup>. These need not coincide with orthographical words: multi-word basic expressions are allowed (see Schmerling 1983 for a presentation of multi-word basic expressions in a categorial algebra; also Culicover et al. 2017). Crucially, we argue that the theory of workspaces is a theory of the lexicon as much as of syntax: we contend that syntactic operations apply *to* (not *in*) the workspace, the initial state of which we call the ‘lexicon’ (more on this in **Section 3**). This is so because, in our view, the initial state of the workspace is an associative network of basic expressions<sup>6</sup>: a lexical space. These expressions are related in syntactic structures; we need to propose a format that allows this to happen.

---

<sup>5</sup> Schmerling (2018: 16) defines that

‘The basic expressions of L are simply the expressions that are not derived by any operation –they can be thought of as comprising the language’s lexicon. If L has a non-empty set of operations (as any natural language does), the outputs of those operations are derived expressions’.

The set of basic expressions is indexed by a set of categories  $Cat = \{N, V, A, P, \dots\}$ . For convenience, we will use  $Cat_X$  where X is a variable over members of Cat. These categories can be seen as abbreviations of a more articulated system (see fn. 9).

<sup>6</sup> In the present view, the theory of syntax is, explicitly, a theory of a system of expressions and relations. See e.g. Epstein (1999: 317-318); Postal (2010: 4-5); Schmerling (2018: 27, ff.) for a variety of views on this vein.

We follow Sarkar and Joshi (1997) and Gorn (1967a, b) in assuming a set of uniquely identifying addresses: as mentioned above, the set of addresses indexes the set of basic expressions. Let  $E$  be a basic categorematic expression of the language (see Schmerling 2018: 151, ff.), then  $\{E\}$  is the uniquely identifying address of  $E$ . Essentially, addresses allow us to uniquely identify expressions regardless of syntactic context, not unlike a direct access icon we may create in an operative system that uniquely identifies a file and always accesses it regardless of where the icon is located. In our analogy, the content of an address would be a file; here, the content of the address assigned to a basic expression is the semantic value of that expression (in the sense of Dowty et al. 1981; Heim and Kratzer 1998 and others):  $\llbracket E \rrbracket$  is the semantic value of  $E$ . This means that when a node appears in a complex object, that node is assigned a unique identifier that is independent of the syntactic context in which that node appears. There is a single address for each elementary semantic value and a single elementary semantic value for each address (syncategorematic expressions -e.g., infinitival *to-* have no semantic values, and are not assigned addresses). This entails that, in  $[b, [a, b]]$  (departing from set-theoretic notation), we use the address  $\{b\}$  twice: there are two calls for the same semantic value in distinct syntactic contexts. No operation such as FORMCOPY or condition such as STABILITY is required (cf. Chomsky 2021: 17). Given a one-to-one relation between addresses and nodes (and between addresses and semantic values), the structure contains only one expression  $b$  with address  $\{b\}$ . There is no need to multiply elements in the representation by having two  $b$ 's: this is an artefact of the set-theoretic foundations of Minimalism. We want to define structures where syntactic dependencies between addressed expressions can be adequately characterised. What formal device, if not sets, delivers the desired result?

This takes us to our second substantive commitment, also anticipated above: derived structures in the workspace are graphs, not sets. A graph is a set  $G = (V, E)$ , where  $V$  is a set of vertices and  $E$  is a set of edges.  $v \in V$  is a vertex, and  $e \in E$  is an edge. An edge  $e$  joining vertices  $a$  and  $b$  is notated  $e = \langle a, b \rangle$ , and  $a$  and  $b$  are said to be *adjacent* vertices. If edges in  $G$  are 'one-way roads' connecting a *head* and a *tail*, they are referred to as *arcs*, and  $G$  is a *directed* graph (or *digraph*)

(van Steen 2010; Wilson 1996)<sup>7</sup>. In this view, syntactic operations establish dependencies between nodes corresponding to basic expressions and define formal objects known as topological graphs (representations of graphs in a plane). For reasons that will become clear shortly, let us refer to the minimal neighbourhood of a lexical predicate as an ‘elementary graph’. The aforementioned ‘syntactic contexts’ can now be defined as the set of nodes that a node is directly connected to (either as the head or tail of an arc): in an irreducible elementary graph, a predicate will be directly connected to its arguments (for context, BPS-style trees are not irreducible, in that they contain multiple tokens of a category in the form of multi-segment categories). Viewing syntactic structures as digraphs in the workspace allows us to recover the asymmetry of structure building and selection: elementary graphs are minimal units of argument structure (see also Chomsky 2020a: 49; Frank 2002: 55). Explicitly, we propose to replace

$$11) \text{ Merge}(X, Y) = \{X, Y\}$$

with

$$12) \text{ Merge}(X, Y) = e\langle X, Y \rangle$$

where  $X, Y$  are uniquely indexed points in the workspace, and either (i)  $X$  selects  $Y$  (e.g.,  $X \in \text{Cat}_V, Y \in \text{Cat}_N$ )<sup>8</sup> or (ii)  $X$  modifies  $Y$  (e.g.,  $X \in \text{Cat}_{Adv}, Y \in \text{Cat}_V$ )<sup>9</sup>. Unlike (11), (12) defines an asymmetric order between  $X$  and  $Y$ , which allows us to capture (among other things) subcategorisation and argument structure: a functor will always dominate its arguments, and an  $n$ -place predicate will have outdegree  $n$ . Note, however, that the order imposed over nodes in (12) is not precedence (cf. Kayne

---

<sup>7</sup> Exponents of graph-theoretic approaches to syntax include Zwicky and Isard (1967), Peters and Ritchie (1981), McCawley (1968, 1982a, b), Huck (1984), Morin and O’Miley (1969), Kuroda (1976), Johnson and Postal (1980), Postal (2010), Gärtner (2002, 2014), Kural (2005), McKinney-Bock and Vergnaud (2014), among others.

<sup>8</sup> See also Zyman (2023) for a graph-theoretic definition of Merge that also depends heavily on the satisfaction of selectional properties. Zyman’s Merge, like classical phrase markers, does not define a direct relation between  $X$  and  $Y$  (but rather between  $Y$  and a ‘reflection’ of  $X$ :  $X$ ’s reflection is distinct from  $X$  but everything that happens to  $X$  also happens to its ‘reflection’, such as the satisfaction of a selectional feature).

<sup>9</sup> These categories could be defined recursively, as in Categorical Grammar. In that case, *selection* always relates an expression of category  $X/Y$  with an expression of category  $Y$  (or  $X/(X/Y)$ , depending on what the functor is), and *modification* always relates an expression of category  $X/Y$  with an expression of category  $(X/Y)/(X/Y)$  (i.e., modification does not change the category of its input). See Dowty (2003).

2022: 10; we agree with Chomsky in that linear order may vary independently of structure, depending on exactly what relations are conveyed by structure): the output of Merge in the present view is ordered inasmuch as subcategorisation creates an asymmetry between selector and selectee (asymmetry that is represented in various ways, including feature descriptions, in e.g. Wurmbrand 2014; Stabler 2011; Zyman 2023).

Thus, as the result of merging (*run*, *John*) we define an irreducible graph like (13), where there is a directed edge from a predicate to its argument (cf. McKinney-Bock and Vergnaud 2014):

$$13) \quad \{\text{run}\} \longrightarrow \{\text{John}\}$$

The directed edge  $e\langle\text{run}, \text{John}\rangle$  is not equivalent to the unordered set  $\{\text{run}, \text{John}\}$ , which gives no information about selection or predicate-argument relations: here, order encodes selection (but not precedence). If we go back to the BPS structure for *Mary saw John*, we see that *Mary* and *John* are both dominated by a node labelled *saw*. As Osborne et al. (2011) observe, the BPS representation (and even more so its radical label-less variants) takes Minimalism in the direction of Dependency Grammars, something we capitalise on. Under present assumptions, a diagram for the maximally simplified structure we can assign to the string *Mary saw John* would be (omitting functional structure for now) the directed graph in (14a), generated by means of the derivation in (14b):

$$14) \quad \begin{array}{l} \text{a.} \\ \begin{array}{c} \{\text{saw}\} \\ \swarrow \quad \searrow \\ \{\text{Mary}\} \quad \{\text{John}\} \end{array} \\ \\ \text{b. Merge}(\text{saw}, \text{John}) = e\langle\text{saw}, \text{John}\rangle \\ \text{Merge}(\text{saw}, \text{Mary}) = e\langle\text{saw}, \text{Mary}\rangle, e\langle\text{saw}, \text{John}\rangle \end{array}$$

The structure grows, yes, but at any point only two basic expressions are Merged: arcs' heads and tails are necessarily basic expressions. There is no derivational step that merges a basic expression with a complex structure (i.e., there is no 'Merge(*John*,  $\langle\text{saw}, \text{Mary}\rangle$ )'), but the graph grows nonetheless. As in the BPS representation, both *John* and *Mary* are immediately dominated by a node indexed *saw*,

but unlike BPS, there is only one such node: departing from set theory to embrace irreducible graphs defined in the workspace allows us to eliminate multi-segment categories as well as labels and projection (see Collins 2002; Seely 2015 for discussion). But it is not just nodes that are ordered (by means of arcs): we contend that arcs themselves are ordered (Krivochen 2023b: Chapter 5). Assuming standard bottom-up structure building, this order mirrors the derivational order of Merge, such that we can define the set of ordered arcs in (14) thus:  $G = \langle e\langle \text{saw, Mary} \rangle, e\langle \text{saw, John} \rangle \rangle$ . Note that the BPS diagram features a two-segment category *saw* that we can eliminate if the aim is to have irreducible structures in the workspace, with no labels or projection<sup>10</sup>, <sup>11</sup>.

This format for syntactic structure allows us to compose local neighbourhoods straightforwardly: if nodes  $v_1$  and  $v_2$  on distinct neighbourhoods  $T$  and  $T'$  ( $v_1 \in T$  and  $v_2 \in T'$ ) are assigned the same address, then the composition of  $T$  and  $T'$  (call it  $T''$ ) will collapse those nodes into one, call it  $v_3$ :  $v_3 \in T''$ , for  $\{v_1\} = \{v_2\} = \{v_3\}$ . The relevant criterion to collapse nodes is identity of addresses. In other words: the composition of local neighbourhoods takes the form of graph-theoretic union: let  $V_1$  and  $E_1$  be the set of nodes and edges, respectively, in a graph  $G$ , and  $V_2$  and  $E_2$  the set of nodes and edges in  $G'$ . Then,  $G \cup G' = (V_1 \cup V_2, E_1 \cup E_2)$  (van Steen 2010: 29; Wilson 1996: 10). Node sharing in structure composition has a pedigree in TAGs (Han and Sarkar 2017; Kallemeier, 2004; Sarkar and Joshi 1997). Karttunen and Kay (1985) use the term ‘structure sharing’ for a process very similar to this one, but restricted to binary trees representing feature structures; this operation has also been used extensively in HPSG (Pollard and Sag 1994: 19; Müller 2015) and LFG (Alsina 2008; Börjars et al. 2019: 103). We can illustrate the results of the composition of local graphs as structure sharing, applying at the root (15a) or at non-root nodes (15b) (in what follows we will omit address notation, presupposing it: for any expression  $E$ , we will use  $E$  instead of  $\{E\}$ ):

---

<sup>10</sup> In this arc ordering, it is possible to encode further information, such as grammatical function (Krivochen 2023b: Chapter 5). Specifically, we can map the order between arcs to the grammatical function hierarchy (Keenan & Comrie 1977; Bell 1983: 148), of wide application in Relational Grammar and its developments (Arc Pair Grammar and Metagraph Grammar), as well as HPSG (Müller 2015: §2) and LFG (Dalrymple et al., 2019: Chapter 2): here,  $\langle e\langle \text{saw, John} \rangle, e\langle \text{saw, Mary} \rangle \rangle$  would be mapped to  $\langle 1/\text{Subject}, 2/\text{Object} \rangle$ .

<sup>11</sup> As observed in Krivochen (2023a, b: Appendix), the corresponding BPS description can be reduced to (14) via *edge contraction*, an operation made available by the formalism.

15) a.

b.

Anticipating discussion from **Section 4**, the syntactic interpretation of a derived graph such as T'' in (15b) is straightforward: a single expression C establishes grammatical relations with predicates A and E, each defined within an elementary graph and preserved after composition. Note, incidentally, that in defining T and T' there is no need to resort to parallel workspaces: each single-rooted structure defines a local domain within WS, with the root being the highest-order functor in that domain<sup>12</sup>. Under these assumptions about structure composition, non-monotonic applications of Merge do not differ substantially from monotonic applications in their formal properties: in the non-monotonic case, Merge applies to expressions which are themselves part of distinct neighbourhoods (as in (15b)). The opacity effects that seem to emerge from non-monotonicity (Uriagereka 2002, 2012) would be a consequence, in the present view, of the requirement that all syntactic dependencies

<sup>12</sup> A related approach can be found in Uriagereka (2008: 257), Krivochen (2015a: 560; 2018), Mori (2005: 3), and especially Saddy (2018). In these works (in one way or another) each application of Merge increases the dimensionality of the structure, defining manifolds of increasing complexity in the workspace. Those approaches are, so far as we can see, compatible with our current characterisation of the workspace. In the present implementation, however, the dimensional complexity of the structure itself does not change, as all we are doing is connect points in the workspace.

be defined at the level of local neighbourhoods of lexical heads, as in lexicalised Tree Adjoining Grammars (LTAGs):

Fundamental TAG Hypothesis (Frank 2002: 22)

Every syntactic dependency is expressed locally within a single elementary tree

What LTAGs call ‘elementary trees’ are defined as the extended projection of lexical heads (Frank 2002, 2013), which is exactly what we intend to have in our ‘elementary graphs’: these are *minimal* in that they are strictly large enough to express all syntactic dependencies required by a lexical predicate which we will refer to as the *anchor* of the elementary graph (cf. Frank 2006: 150-152)<sup>13</sup>. These requirements include subcategorisation and theta grids. An elementary graph, then, will contain (a) a single lexical predicate (the anchor of the graph), (b) all functional heads modifying that predicate, and (c) all arguments subcategorised by that predicate (Krivochen 2023b; Krivochen and García Fernández 2019). These structures will be the domains where all syntactic relations are defined. Adopting the Fundamental TAG Hypothesis as a condition on the well-formedness of local structures means that (i) if the same address occurs in distinct elementary graphs, it must enter syntactic dependencies in each of these (and, as we shall see, a single addressed expression may establish more than one relation within an elementary graph), and (ii) syntactic relations, once established, cannot be disrupted (but new relations can be built on top of existing ones)<sup>14</sup>. In turn, conceiving of the composition of local neighbourhoods as graph union allows us to have derived graphs with multiple calls for the corresponding semantic value: we say that the node assigned that multiply called address is *shared* between elementary graphs. Note, however, that calling for an

---

<sup>13</sup> The concept of elementary graph could also be related to Chomsky and Lasnik’s (1995: 102) definition of ‘complete functional complex’ (CFC), ‘where a CFC is a projection containing all grammatical functions compatible with its head’. Chomsky and Lasnik’s ‘head’, in the present context, would be the anchor of an elementary graph.

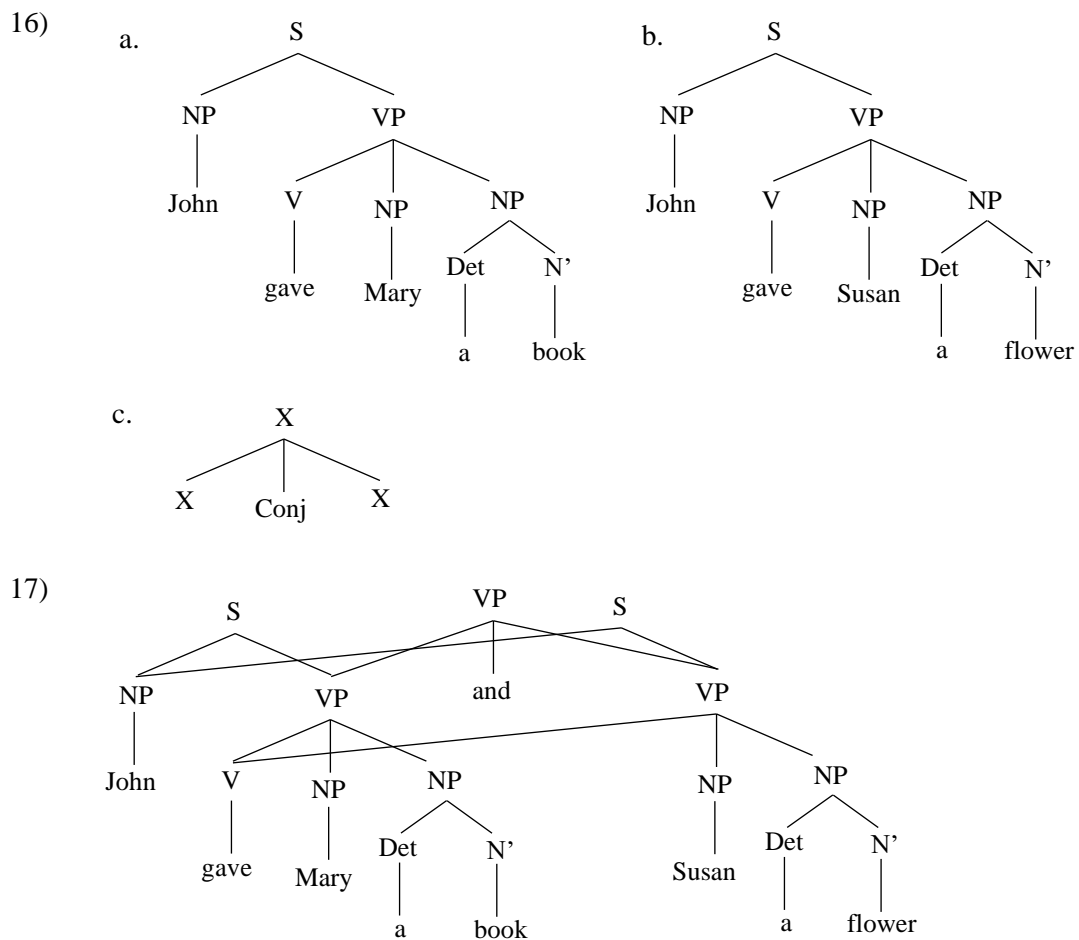

<sup>14</sup> Kroch (2001) makes this requirement explicit in TAGs:

‘we never want to allow derivations under which thematic roles, once established, are altered by further adjunctions, and we will block such derivations by, in every tree, placing a particular local constraint on every node that is assigned a thematic role by a governor’ (Kroch 2001: 11).

To the extent that subcategorisation and theta marking are lexical requirements, the idea that lexically governed relations are not disrupted throughout the derivation can be related to Lasnik and Uriagereka’s (2005: 53, 112) *Conservation Laws*.

address more than once in a domain works both for elementary and derived graphs, as the only condition is that ‘corresponding objects in the corresponding expressions have the ‘same’ addresses’ (Gorn 1967a: 214). Distinct configurations subject to distinct conditions arise in each case, as we will see in **Section 4**.

Let us give an example of the system at work, using traditional X-bar trees: the derivation of *gapping* in TAGs. The addressing system, plus composition at the non-root (TAGs explicitly do not abide by the Extension Condition; see Frank and Hunter 2021), allows Sarkar and Joshi (1997) to compose the trees in (16a, b) with the coordination schema in (16c) (where X stands for any category label) to output the derived structure (17):

As Chomsky, Collins and Groat, and others have emphasised, (17) does not correspond to a legitimate set-theoretic object, but it is a perfectly well-formed graph-theoretic one, and -as we will highlight in

**Section 4-** structure sharing is unavoidable given our addressing system. The idea that points in the workspace are indexed by a set of uniquely identifying addresses also has important consequences for the analysis of long-distance dependencies and binding (**Section 4**).

## 2.2 Some technical consequences

The definition of the ‘projection’ of a head as the neighbourhood of that head defined in the workspace allows us to clarify several issues: in particular, we can shed some light on the concept of *edge* (of a syntactic domain). In an otherwise impenetrable domain (for example, a phase), the edge is a structural position that is accessible for operations triggered by a head external to that domain. What exactly constitutes the edge of a domain and is therefore (i) accessible for external operations and (ii) excluded from Transfer has been a problematic issue. Accessibility is a central concept in current generative theory. In this context, it is worth asking whether there are properties of the workspace which can deliver locality and accessibility, as well as a natural definition of distance, or whether these must be defined and characterised in different terms. Provided that all syntactic dependencies must be defined within elementary graphs and these are lexically anchored, it is lexicalisation that delivers not only a workable concept of locality, but also determines the size of grammatical building blocks. Accessibility, although related to lexicalisation, is a different matter, as is distance.

In what pertains to accessibility, this is another point where the definition of local syntactic domains in terms of neighbourhoods of heads, as defined above, pays out theoretically and empirically. Recall that the neighbourhood of X may be open or closed. In this context, we can propose the following condition: if WP is accessible from outside XP, and WP is a syntactic object dependent of X, then we can define the neighbourhood of X,  $U(X)$ , to be open and WP to be the edge of  $U(X)$ . Crucially, it is possible for interior points of a set to be limit points as well: these are what phase theory refers to as ‘edges’. Complements, on the other hand, would be interior points that are not limit points (of the neighbourhood of X in WS).

Accessibility is not defined in Chomsky (2019, 2020a, b) and related works beyond the Phase Impenetrability Condition (other than the claim that ‘if something was accessible to MERGE in WS it

has to still be accessible in WS'', Chomsky 2020a: 56), but if we take the idea that operations apply in a workspace seriously, then we can provide an answer: accessibility is defined in terms of a syntactic object A being contained in an open neighbourhood if it is to be targeted by an operation triggered by a distinct syntactic object B. Closed neighbourhoods prevent accessibility<sup>15</sup>.

### 3. Metric spaces and distances in syntax

We defined what a space is in a very general way: a set of points and a set of neighbourhoods, plus a set of axioms allowing specific relations between these. We further defended that syntactic workspaces are topological spaces. Now we need to examine some properties of spaces in terms of the axioms that define the possible relations between these points. This is important because different sets of axioms define different spaces, and since the core idea of this paper is that the properties of the workspace determine the kinds of syntactic relations that can be defined between expressions, we must get into some detail about types of spaces. Intuitively, points in a space can be close or far apart to different degrees: we can call the function that defines just how close or far apart points are the *metric* of the space (Willard 1970: 16; Sutherland 2009: 39). Here we differentiate between two such spaces:

- |   |  |
|---|--|
| <p>18) For <math>x, y, z</math> points in a topological space <math>S</math>, <math>S</math> is <i>metric</i> iff:</p> <ul style="list-style-type: none"> <li>a. <math>d(x, y) &gt; 0</math> if <math>x \neq y</math> (<i>positive property</i>)</li> <li>b. <math>d(x, y) = 0</math> iff <math>x = y</math> (<i>identity property</i>)</li> <li>c. <math>d(x, y) = d(y, x)</math> (<i>symmetric property</i>)</li> <li><b>d. <math>d(x, z) \leq d(x, y) + d(y, z)</math> (<i>triangle inequality</i>)</b></li> </ul> | <p>For <math>x, y, z</math> points in a topological space <math>S</math>, <math>S</math> is <i>ultrametric</i> iff:</p> <ul style="list-style-type: none"> <li>a. <math>d(x, y) &gt; 0</math> if <math>x \neq y</math> (<i>positive property</i>)</li> <li>b. <math>d(x, y) = 0</math> iff <math>x = y</math> (<i>identity property</i>)</li> <li>c. <math>d(x, y) = d(y, x)</math> (<i>symmetric property</i>)</li> <li><b>d. <math>d(x, z) \leq \max\{d(x, y), d(y, z)\}</math> (<i>ultrametric inequality</i>)</b></li> </ul> |
|---|--|

Above we suggested that distance is a crucial notion in theoretical syntax; now we will see how a formal definition of workspace in topological terms can help us capture the theoretical insights. The

---

<sup>15</sup> Having disjoint closed neighbourhoods for  $x$  and  $y$  entails that  $x$  is not accessible to  $y$  and  $y$  is not accessible to  $x$ ; furthermore, no point in the neighbourhood of  $x$  is accessible to any point in the neighbourhood of  $y$  and vice versa. In syntactic terms, we may think of completely opaque domains: a syntactic term all of whose terms are inaccessible to operations triggered from outside that term. It is not clear whether such terms exist in natural language, but this is an empirical question. Plausible candidates for syntactic objects with *closed* neighbourhoods are those that cannot be embedded (and thus not even their root can be targeted by syntactic rules): imperatives (Schmerling 1982), vocatives, and interjections (Chomsky 2008: 139).

distance  $d$  over a set  $X$  is a function defined on the Cartesian product  $X \times X$  (producing a set of ordered pairs of members of  $X$ );  $d$  will be called a *metric* iff properties (a-c) plus the triangle inequality hold. The triangle inequality is a crucial property: it determines that distances in metric spaces sum: informally, if  $x$  is  $m$  units away from  $y$  and  $y$  is  $n$  units away from  $z$  in a segment defined in  $X$ , then  $x$  is  $m + n$  away from  $z$ . This is an essential property of metric spaces, because it allows us to formulate the notion of *closeness* in comparative terms, such that  $x$  is closer to  $y$  than  $z$  if  $d(x, y) < d(y, z)$  (i.e., if  $m < n$ ). In the system sketched in the previous sections, the identity property is intimately related to the addressing system: for  $E, E'$  expressions,  $d(E, E') = 0$  iff  $\{E\} = \{E'\}$ . This condition underpins the idea that the composition of neighbourhoods, implemented as graph union, delivers structure sharing, and in fact enforces it: if an address is called in two or more elementary graphs that undergo composition, the derived graph will contain a single node with that address, which is always at 0 distance from itself. Two properties of metric spaces are crucial for our purposes: first, we can keep distinct points (i.e., expressions with distinct addresses) at non-zero distances from one another<sup>16</sup>. Second, the distance function can take arbitrarily many values, and distances sum.

The fact that distances between points vary and sum distinguishes metric from *ultrametric* spaces. Gajić (2001: 96) provides the following characterisation (see also Sutherland 2009: 41):

**‘Remark:** Let [a topological space]  $X \neq \emptyset$ , [with a] metric  $d$  defined on  $X$  by

$$d(x, y) = \begin{cases} 0, & \text{if } x = y \\ 1, & \text{if } x \neq y \end{cases}$$

[then, the] so-called discrete metric is ultrametric’

Since distances between points are either 0 or 1, ultrametric spaces preserve topological distinguishability but all distinct points are *equidistant*, at distance 1 from each other. One of the main things we want a formalisation of workspaces to do for us is capture the idea that two distinct points  $x$  and  $y$  in WS can be arbitrarily near or far apart (however distance is calculated), but never have 0 distance.  $x$  and  $y$  can only have a 0 distance *iff*  $x = y$ ; this is crucial for our purposes of defining a

---

<sup>16</sup> This requirement is enough to discard *pseudometric* spaces as formalisations for syntactic WS, since in a pseudometric space  $d(x, y)$  can be 0 even if  $x \neq y$ .

notion of workspace that is syntactically usable. In other words, we want a space that preserves distinguishability between expressions with distinct addresses and in which variable distances can be defined unambiguously: locality conditions in the establishment of dependencies are based on the idea that some syntactic objects are closer to each other than to others.

One important, yet implicit, assumption in the definition of MERGE in recent work is that the mapping between WS and WS' does not modify the properties of WS: it just expands the set of accessible elements by one (Chomsky 2021; Kitahara 2021). We depart from this assumption, arguing instead that the establishment of syntactic relations between points in WS in fact modifies the topological properties of WS, but never its size. A derivation is a dynamical process whereby the topology of WS is disrupted, and a number of locally stable structures are built. Building on the classical definition of a derivation as a finite sequence of steps, and borrowing terminology from dynamical systems theory, let us refer to the initial state of WS as its *ground state* and the final state of WS with respect to a derivation as a *stable state* (possibly one of many, in which case we speak of *multistability*; Kelso 2012). The ground state of WS, in the present view, is what we usually refer to as the Lexicon: the set of basic expressions of the language, indexed by a set of addresses. This is ground zero for a derivation. A local description of the WS's stable state characterises a syntactic output.

Let us focus on the initial state of WS. Before the selection of a 'lexical array' to derive a specific sentence, we contend, all expressions are equally accessible and no two expressions are more closely related than any other two<sup>17</sup>. Distinct expressions are distinguishable in the lexicon, as the addressing system is independent from the topological properties of WS. However, as far as distances are concerned, all distinct expressions are equidistant and equally likely to be selected<sup>18</sup>. What we have

---

<sup>17</sup> The selection of expressions is so far as we can see an unavoidable step (but see Chomsky et al. 2019), and one that requires external influence: a mechanism that defines an arc  $\langle x, y \rangle$  given expressions  $x$  and  $y$  is of little use in syntactic analysis if we do not know what expressions are to be used. However, what expressions are selected is a consequence not of the definition of workspace or its dynamics, but of the intention that a user of the system may have (in connection to the expression of a conceptual structure, for instance). Similarly, whereas linguistic experience may reinforce certain connections in the ground state of the workspace (just like exposure to sensoria creates associations in other cognitive systems), that is not a property of the workspace we are describing, but a consequence of implementing (or 'embodying') that system.

<sup>18</sup> This does not entail, evidently, that any choice may lead to a *convergent* derivation. An issue that immediately arises is how selection proceeds throughout the derivation (once the 'seed' of a local derivation, necessarily a lexical predicate, has been selected). Having Merge satisfy predicates' selectional properties (subcategorisation

just described is precisely an ultrametric space. We could justify the choice of ultrametricity as the topological characterisation of the initial state of WS in terms of (i) preserving distinguishability between distinct basic expressions, and (ii) not imposing a variable metric over these expression in the absence of syntactic relations. Both reasonable assumptions about the lexicon, arguably. However, we can also ask what conditions imposed over the linguistic system would deliver ultrametricity as the initial state of WS. We will briefly address this question in the following section.

### 3.1 Frustrated language

The idea that derivations are dynamical processes, with ground states and (meta or multi-)stable states, is intimately related to recent work which has identified a *dynamical frustration* at the core of language, building on old insights. As defined in Binder (2008), a dynamical frustration emerges when a complex dynamical system is subject to mutually incompatible requirements, which gives rise to a form of dynamical instability. For example, a complex system may display local forces (e.g., dissipative) which counteract global (e.g., cooperative) forces; this is a *scale frustration*:

Figure 1: Scale frustration (from Binder 2008: 322)

The concept of dynamical frustration appeared in physics in the context of the study of spin glasses (Stein and Newman 2011). These are magnetic systems in the form of lattices in which electrons are subject to a pairwise antialignment constraint such that no two neighbouring electrons can have the same spin (up or down), which makes the system locally frustrated: there is no stable mode that satisfies the antialignment constraint for all electrons. This is a *geometrical frustration*:

---

and thematic selection) seems like a reasonable way to do this. In contrast, it is hard to see how ‘free’, ‘blind’ Merge can be implemented in an empirically and computationally feasible manner (indeed, Minimalist Grammars do not use free Merge).

Figure 2: geometrical frustration

As Rammal et al. (1986: 771, ff.) argue, ‘The crucial ingredients in these models [of spin glass] are disorder [entropy] and frustration.’. Since the system cannot achieve a stable state globally, multiple locally optimal solutions appear, and the system oscillates between metastable states<sup>19</sup>. In addition to spin glass, the concept of *dynamical frustration* has also been fruitfully applied to self-organising biological systems (Yang 2011), neural assemblies (Gollo and Breakspear 2014), protein structure (Nerukh 2009), and computability (Binder 2008).

In linguistic terms, the idea put forth in Uriagereka (2012, 2014); Saddy (2018) and related works (and which can be traced back to Tesnière 1959: 21) is that morphophonology and semantics impose mutually incompatible requirements over syntactic representations: ‘flatness’ and low-dimensionality on the PF side (e.g. Scheer 2013; Idsardi and Raimy 2013) and multidimensionality and higher-level relations in the LF side (e.g. Hinzen 2009: 31; also the references on fn. 12). Uriagereka’s (2012, 2014) discussion of dynamical frustration in language (which he considers ‘third factor’) refers to as a *hiatus*, a ‘discontinuity’ (a clash) between bottom-up semantic substance and left-to-right phonological organisation in a revised Minimalist architecture<sup>20</sup>:

---

<sup>19</sup> In dynamical systems theory, a metastable state is a state other than the minimum energy state which is easy to destabilise. The metricisation of the workspace must be metastable because the structure so delivered is transient. Saddy (2018), under the assumption that syntactic operations create structures of increasing dimensional complexity (see fn. 12), argues that metricisation is a consequence of the intersection of these structures in the workspace, structures which may then reach critical dimensionality and destabilise along the dimension where forces begin to fade (Carr 2006). The result is a lower-dimensional manifold that expresses the core properties of its high-dimensional version, and which can enter further computations before reaching critical dimensionality again. After dimensional compression, the system goes back to its minimum energy state, which is idealised here as an ultrametric space.

<sup>20</sup> Roughly, DS is ‘an array of conceptual structures’ (2014: 367), PF is a ‘designated class of speech objects’, and LF is ‘a designated class of chains’ (2008: 6).

Figure 3: Inverted Y-model vs. CLASH architecture (taken from Uriagereka 2014: 367)

Given the conflicting output conditions that sound and meaning systems impose over the space where syntactic structure is defined, we argue that instead of settling to equilibrium (Spencer et al. 2009: 109), the system is in permanent oscillation between metastable states (Binder 2008: 322). In the present context, this oscillation takes place between high-dimensional vs. low-dimensional computation, and global vs. local requirements.

If, following Saddy, Uriagereka, a.o., we propose that core structural properties of language are the result of a dynamical frustration, then the kind of topology delivered by dynamical frustration should be an adequate characterisation of the initial state of the syntactic workspace. Thus, we can tackle the issue ‘from the other side’: what kind of spaces do dynamical frustrations characterise? Murtagh (2004: 168) puts it in the following terms:

“‘Frustrated optimization problems’” are ultrametric, and have been shown as such for spin glass and related special cases.’

If the conditions under which syntax operates are defined by dynamical frustration, then language may well be one of these ‘special cases’, from the perspective of both computation and its neurophysiological underpinnings. However, the proposal in this paper is that the topological properties of the workspace do not remain constant throughout the derivation: an adequate description of the syntactic workspace, we argue, takes the form of the characterisation of a dynamical system. Structural descriptions are snapshots of (meta)stable states of that system. We may summarise the previous discussion thus: a *dynamical frustration* can deliver an ultrametric space, the initial state of the syntactic workspace (Saddy 2018: 317), which is metricised by means of syntactic operations

whereby points in the space (basic expressions) enter structural relations. These structural relations are defined in local domains, the neighbourhoods of lexical predicates.

What does a (meta)stable state of WS look like? As observed above, much work in generative grammar suggests that an adequate characterisation of syntactic structures requires being able to sum distances and determine, given syntactic objects X, Y, Z in a structural description, whether X is closer to Y than Z: as mentioned before, conditions like Relativised Minimality (Rizzi 2016), Minimal Link/Shortest Move, Attract Closest (Chomsky 1995b) and Minimal Search (Chomsky 2004 et seq.) among others are, crucially, based on the idea that terms in a structural description can be at variable distances from one another, with some objects being closer than others. In addition to variable distances, we must evidently keep the distinguishability of distinct (indexed) expressions. In this context, *metric* spaces become the natural option as a characterisation of WS once structure has been built (see also Martin et al. 2019: their Hilbert space is a vector space endowed with a metric; Roberts 2015, however, proposes an ultrametric analysis of X-bar trees, which entails an ultrametric syntax). Structural descriptions (here, digraphs) are characterisations of local regions of a metricised WS.

Once syntactic relations are defined via  $\text{Merge}(X, Y) = e\langle X, Y \rangle$ , where X and Y are basic expressions (and only then), we can define variable distances between nodes in a structure: this is how elementary graphs are built, and how the workspace gets metricised:

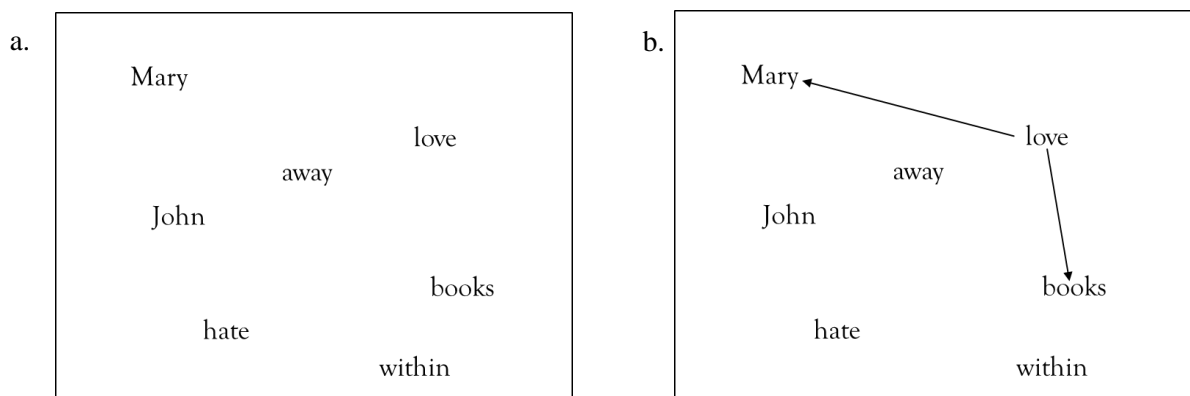

Figure 4: graphs in WS

In Figure 4, (a) is a crude illustration of an ultrametric space: it corresponds to the lexicon, an associative (but unstructured) network. No syntactic relations yet exist between basic expressions,

which are all equidistant. In (b), we have selected some expressions, one of which is a lexical predicate with specific subcategorisation properties: it takes two arguments, and assigns a thematic role to each as part of structure building (cf. Chomsky, 2021: 18). As in analyses such as Stabler (2011), Wurmbrand (2014), Zyman (2023), and Krivochen (2023a) (among others), Merge satisfies these selectional properties as it establishes syntactic relations between *love*, *Mary*, and *books*: we define a digraph  $G = \{E, V\}$  in the workspace, where  $V = \{\textit{love}, \textit{Mary}, \textit{books}\}$  (basic expressions) and  $E = \langle e\langle \textit{love}, \textit{Mary} \rangle, e\langle \textit{love}, \textit{books} \rangle \rangle$  (arcs from the predicate to its arguments). Now, *love* is closer to *Mary* and *books* than to any other point: this disrupts the ultrametricity of the lexicon and delivers a graph in metric space. Figure 4b diagrams a space that has been locally metricised. Once we have that local metricisation, other linguistic conditions follow. For instance, Saddy (2018) argues that given the ultrametric inequality it is not possible to define linguistically relevant notions like ‘edge’ in ultrametric trees: the head is equidistant to every node within the tree and what we would call (in X-bar theoretic terms) ‘specifier’ and ‘complement’ are also equidistant. However, if the space is metricised, we can define (open) neighbourhoods of lexical heads, which constitute the building blocks of syntax in a lexicalised grammar. As in **Section 2**, we may distinguish *interior* and *boundary* points (and their neighbourhoods) once the space has been metricised, with familiar consequences for the definition of syntactic dependencies and structure composition: Substitution and Adjunction in TAGs are defined in terms of their target (a node in the frontier of an elementary tree or an internal node respectively; see Frank 2002; Kallemeyer 2004).

It is important to remember that in our perspective there are not *two spaces*, lexicon and syntax: syntactic operations apply to the lexical space (see also Stroik and Putnam 2013: 54). In other words: establishing syntactic relations between basic expressions modifies the topology of the lexicon, delivering a set of directed graphs in a metric space. Merging X and Y entails (i) bringing X and Y closer together than they were and (ii) defining an asymmetric relation between them (in McKinney-Bock and Vergnaud 2014, for instance, these relations can be either Selection or Checking, with which they annotate arcs). Now the metric between any two points in the workspace cannot be just two-valued (0 or 1): syntactic composition of X and Y ( $X \neq Y$ ) puts X closer to Y than

to any other point. If Z is merged to X, X will be closer to Y than Z will be, but still Z will be closer to Y than a point in the workspace that is not part of this local neighbourhood. Properties of the space where a structure is defined constrain the relations that can hold between expressions in that structure and the operations that can apply to it .

In **Section 4** we address the issue of how local structures are put together, since so far we have defined a set of elementary structures (the neighbourhoods of lexical predicates) and hinted at the existence of composition operations (based on graph union / structure sharing) but we have not operationalised them. The next section spells out some consequences of our approach for the theories of locality and binding in derived structures.

#### **4. Doing syntax to the workspace**

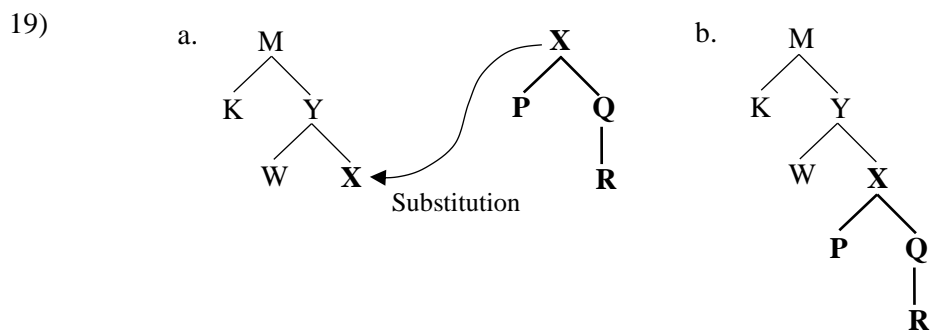

Let us summarise the situation so far. We have a characterisation of the workspace to which syntactic operations apply and, in that space, we have the expressions that appear in structural descriptions defined as points within said space. The initial state of WS is ultrametric: an associative network in which all basic expressions are equidistant. Through the application of syntactic operations, which generate directed graphs with expressions as nodes, this metric space is populated by a set of topological graphs that we refer to as ‘elementary graphs’. These elementary graphs are defined as the minimal unit that contains a lexical predicate (the ‘anchor’ of the elementary graph), its functional modifiers (e.g., auxiliary verbs; Krivochen and García Fernández 2019, Krivochen and Padovan 2021), and its arguments. Each node in an elementary graph, a point in WS, is a categorematic basic expression assigned a uniquely identifying address. Elementary graphs are the neighbourhoods of lexical predicates. If these neighbourhoods are open, elements within one neighbourhood become accessible from other neighbourhoods: this allows for the composition of local neighbourhoods and the formation of complex structures. The remainder of the paper will focus on the mechanisms underpinning the generation of derived syntactic objects.

##### **4.1 Structure composition**

As an introduction to the problem of structure composition, consider the formulation of the so-called Address Issue:

‘Whenever a phrase-marker *K* is divided into complex sub-components *L* and *M* [...], the daughter phrase-marker *M* that spells-out separately must correspond to an identical term *M* within *K*.’ (Uriagereka 2012: 75).

Uriagereka’s requirement proposes a solution to the problem that arises in all models of cyclic structure interpretation: once an input has been chunked and each part has been subject to an arbitrary set of operations, how do we put everything back together to get, for example, a compositional semantic interpretation? A theory of syntax must provide a way to capture structure composition in addition to locality, optimally without having to invoke additional structure in the form of semantically vacuous non-terminal nodes. In looking at composition operations, let us start with Substitution. In traditional phrase structure terms, let *M* be a term, and let *Y* be a term within *M*, with a node *X* in its frontier. Furthermore, let *X* be the root node of a distinct term (not a part of *M*). Then, we can substitute the node *X* in *M* with the sub-tree *X*:

Importantly, Substitution does not create new nodes: (19b) contains a single node labelled *X*. This is consistent with a characterisation of structure composition as graph union, where syntactic objects are indexed by uniquely identifying addresses. Substitution never delivers (19c) (see Frank 2002: 17, ff. for discussion):

This operation is involved in the standard TAG analysis of clausal complementation (Frank 2006: 153; Kroch and Joshi 1985: 27, ff.; XTAG 2001: 91, ff.):

20) John wished [that Mary would forgive him]

(20) features two clauses in a hypotactic relation; each of these corresponds to an elementary graph by virtue of containing a single lexical predicate (more specifically, by being the neighbourhood of a single lexical predicate in WS). The bracketed clause (call it L), whose lexical anchor is *forgive*, is subordinated to the elementary graph anchored by *wish* (call it M). Under standard phrase structure assumptions, the elementary graph of *wish* contains a subject and a placeholder in its frontier that corresponds to the root of the direct object of *wish* (Chomsky 1955: 481, ff., 1995b); the elementary graph of *forgive* contains its arguments (a subject and a direct object) and a functional modifier in the form of the auxiliary *would*. Then, (21) is a phrase-structural derivation of (20) using Substitution:

21) a. [<sub>M</sub> John wished [<sub>L</sub>]]

b. [<sub>L</sub> that Mary would forgive him]

c. [<sub>K</sub> [<sub>M</sub> John wished [<sub>L</sub> that Mary would forgive him]]] (via Substitution targeting L)

In this case, what we have done is link the neighbourhoods of two basic expressions, *wish* and *forgive*, by identifying the same node in both syntactic objects: the address we have called L in M (21a) points to the same object as the address L in (21b), namely, the root of the sub-graph that is a structural description for the string *that Mary would forgive John*.

This is an important point, since it highlights what our definition of workspaces can do for us. In the structural description of (20) there are two distinct objects *John* and *him* only if a structural description is a set of lexical tokens (Uriagereka 2008: 16): in that case, ‘John’ and ‘him’ are lexical tokens introduced at distinct points in the derivation and bearing no relation to each other unless an index says so. This is unavoidable if the lexicon and the syntactic workspace are severed from each other, and structure is strictly set-theoretic (as we saw with (6c)). However, because of how workspaces have been defined here, structural descriptions are specifications of the formal relations between basic expressions defined in a lexically anchored directed graph. Above we emphasised that the composition of local lexicalised neighbourhoods involves structure sharing, in that common addresses in distinct elementary graphs collapse to a single object in a derived structure: structure composition is graph union. Then, we need to revise (21) as in (22), where we substitute the expression *John* with the address  $\{\text{John}\}$ , which uniquely points to the semantic value of *John*:

- 22) a.  $[_M \{\text{John}\} \text{wished } [_L]]$   
 b.  $[_L \text{ that Mary would forgive } \{\text{John}\}]$   
 c.  $[_M \{\text{John}\} \text{wished } [_L \text{ that Mary would forgive } \{\text{John}\}]]$

Once L substitutes for L in M, there are two calls for the address  $\{\text{John}\}$ , each of which belongs to a distinct neighbourhood. Given the definition of Merge in **Section 2.1**, coupled with the assumption that predicates directly dominate their arguments (Osborne et al. 2011; Krivochen 2023b; McKinney-Bock and Vergnaud 2014), in the derived structure (22c) we have a single node  $\{\text{John}\}$  immediately dominated by *wish* and by *forgive*, establishing distinct syntactic relations with each of these predicates. We can sketch a derivation of (20) as in (23), where the order between arcs is determined by the sequentiality of Merge (see also fn. 10). In (23), arguments are immediately dominated by the anchors of the elementary graphs where they occur:

23) Elementary graph 1:

- a.  $\text{Merge}(\text{forgive}, \text{John}) = e\langle \text{forgive}, \text{John} \rangle$   
 b.  $\text{Merge}(\text{forgive}, \text{Mary}) = \langle e\langle \text{forgive}, \text{Mary} \rangle, e\langle \text{forgive}, \text{John} \rangle \rangle$

c. Merge(would, forgive) =  $\langle e\langle \text{would, forgive} \rangle, e\langle \text{forgive, Mary} \rangle, e\langle \text{forgive, John} \rangle \rangle$

d. Merge(would, Mary) =  $\langle e\langle \text{would, Mary} \rangle, e\langle \text{would, forgive} \rangle, e\langle \text{forgive, Mary} \rangle, e\langle \text{forgive, John} \rangle \rangle$

e. Merge( $C_{\text{that}}$ , would) =  $\langle e\langle C_{\text{that}}, \text{would} \rangle, e\langle \text{would, Mary} \rangle, e\langle \text{would, forgive} \rangle, e\langle \text{forgive, Mary} \rangle, e\langle \text{forgive, John} \rangle \rangle$

Elementary graph 2:

a. Merge(wish,  $C_{\text{that}}$ ) =  $e\langle \text{wish, } C_{\text{that}} \rangle$

b. Merge(wish, John) =  $\langle e\langle \text{wish, John} \rangle, e\langle \text{wish, } C_{\text{that}} \rangle \rangle$

c. Merge(T, wish) =  $\langle e\langle T, \text{wish} \rangle, e\langle \text{wish, John} \rangle, e\langle \text{wish, } C_{\text{that}} \rangle \rangle$

d. Merge(T, John) =  $\langle e\langle T, \text{John} \rangle, e\langle T, \text{wish} \rangle, e\langle \text{wish, John} \rangle, e\langle \text{wish, } C_{\text{that}} \rangle \rangle$

It is important to emphasise that despite the fact that there are two lexical predicates, and therefore two elementary graphs, there are not two workspaces: each lexical predicate does define its own neighbourhood, but these are just two regions of the same space. Because the address  $\{\text{John}\}$  is called in both elementary graphs, and *as per* the identity property  $\{\text{John}\}$  is at distance 0 from itself, when these are combined the derived graph contains only a single node addressed  $\{\text{John}\}$ , dominated by the lexical anchors *wish* and *forgive*, of which it is an argument. The relation between T and the external argument, which Minimalism requires for Case reasons, is represented without movement, by means of an edge from T to this argument.

Crucially, in a traversal through the derived structure (22c),  $\{\text{John}\}$  in M is ordered before  $\{\text{John}\}$  in L, since L is embedded in M (i.e., there is a node in M which dominates the root of L): this will become important for pronominalisation, which we will look at shortly. Note that the operation Substitution itself (in classical generative grammar and Minimalism as well as TAGs) can apply because the grammar can identify identical indexed nodes (in a phrase structure tree, the set of nodes is indexed by a set of labels). No additional mechanism or condition (such as Chomsky's 2021 STABILITY) is required to deliver this result, since if nodes on distinct elementary graph T and T' are assigned the same address, then a derived graph T'' defined as the union of T and T' will collapse

those nodes into one<sup>21</sup>. Merge never produces copies (the number of elements in WS never increases during a derivation), it defines arcs between indexed expressions. New relations may be defined throughout the derivation, on top of existing relations.

Importantly, as long as the relevant node receives an interpretation in all elementary graph where it occurs, the neighbourhoods of two or more lexical predicates may share more than one node (see e.g. (17) above). This is precisely what we need for (22): (22a) contains a call for an address (which we called L) that coincides with the root of the graph (22b) in its frontier; in addition to this, there is another common address embedded in both structures, {John}. All syntactic dependencies are established within local neighbourhoods, but these neighbourhoods are open and thus can contain points that also belong to other neighbourhoods. Uriagereka's 'identity condition' is defined here in terms of the addressing system.

We must emphasise that, if syntactic operations are required to yield trees in which an element cannot be dominated by more than a single node (the Single Mother Condition; Sampson 1975) then we are required to multiply the entities in structural descriptions: because syntactic context is defined in terms of dominance, *John* dominated by the root in M and *him* dominated by *forgive* in L already have a mother node each and cannot have another. In Minimalist syntax, each must be a distinct object, introduced at different derivational steps. Under strict set-theoretic assumptions, where M and L are sets of (sets of) syntactic terms, we cannot say that {John} in M and {John} in L ( $\{\text{John}\}_M$  and  $\{\text{John}\}_L$ , for convenience) are the same object or a 'discontinuous' one, since it would entail that {John} both belongs and does not belong to the set L (see Gärtner 2022 for further discussion). However, this multiplication of entities does not arise in the present proposal, as a consequence of the definition of workspace as a topological space: the identification of  $\{\text{John}\}_M$  and  $\{\text{John}\}_L$  amounts to having  $d(\{\text{John}\}_M, \{\text{John}\}_L) = 0$ , which -again- is a direct consequence of a property of the workspace

---

<sup>21</sup> There are interesting connections between our approach and Martin et al.'s (2019) superposition-based chain dependencies (where the interpretation of a chain requires the collapse of multiple occurrences into a single observable one). The main difference is that instead of starting with multiple occurrences of a term (derived via copying) and reducing them to one, the present approach prefers maximally connected nodes in digraphs: nodes are never multiplied to begin with, only edges are.

(the *identity property* (18b)). This is only possible because we are defining graphs in the workspace: an account of the property of displacement in graph-theoretic terms does not need to make filler and gap distinct symbols; it can work with one node visited more than once in a walk through a digraph. A topological perspective on the notion of workspace allows us to simplify the mechanisms of the grammar, in this case dispensing with independent indexing mechanisms for identical terms in distinct syntactic contexts in favour of a property of the workspace.

#### 4.2 Chains, copies, and repetitions

The approach to chain formation in Martin and Uriagereka (2014: 174, ff.) allows for a phrase marker to ‘fold’, collapsing distinct links of the chain into a single object. In their view,

‘Chains are best represented as being comprised of several simultaneous derivational stages, so that in principle they exist in one or the other stage (say, the ‘foot’ or the ‘head’ of the chain, in these instances). To interpret a chain in a particular chain-state  $\rho$  is to collapse the chain in  $\rho$ .’

Consider a case like

24) Which paper did John review?

In Martin and Uriagereka’s view, IM ‘turns [a phrase marker] into a topologically more complex sort of object’ (2014: 175). This complexity is due to the fact that the phrase marker ‘folds’ on itself, delivering a toroid shape. The underlying structure would be (25) (we strikethrough silent occurrences):

25) Which paper did John review ~~which paper~~?

Under current assumptions, the core of Martin and Uriagereka’s analysis can be captured straightforwardly. In the simplest analysis available, the sub-graph with root  $\{\text{which}\}$  (the irreducible expression of which contains  $\{\text{paper}\}$  immediately dominated by  $\{\text{which}\}$ :  $e\langle\text{which, paper}\rangle$ ) is

immediately dominated by both *review* and C, with which it establishes distinct relations: in McKinney-Bock & Vergnaud's (2014) terms, Selection with *review* and Checking with C<sup>22</sup>.

An important consequence of our system is that, as per the identity property and unique indexing, the distance between 'copies' of *which paper* will always be 0, regardless of how much structure is introduced between 'filler' and 'gap':

26) Which paper [did Mary say that Sue suspected that] John reviewed ~~which paper~~?

The derived expression *which paper* is dominated only by *review* and by matrix C in both (25) and (26). Such an analysis captures the core of TAG's Non-Local Dependency Corollary (NDC):

Nonlocal dependencies always reduce to local ones [defined within elementary trees] once recursive structure is factored away. (Frank 2002: 27)

Because they are established at the level of local neighbourhoods, which are units of argument structure, all syntactic dependencies must be local: the object *which paper* is never removed from the neighbourhood of *review*. The relation created between *review* and *which paper* in the directed graph  $G = \langle e \langle \text{review}, \text{John} \rangle, e \langle \text{review}, \text{which} \rangle, e \langle \text{which}, \text{paper} \rangle \rangle$  is not disrupted throughout the derivation: when C is introduced, a new edge  $e \langle C, \text{which} \rangle$  is created via Merge(C, which). No copies are created, since we can call the address  $\{\{\text{which}\}\}$  (which is all we need, since *which* immediately dominates *paper*, allowing a walk from C to *paper*) more than once, and the indexing system implemented in a metric space ensures that any (derived) expression with (derived) address  $\{\{\text{which paper}\}\}$  (computed from  $\{\{\text{which}\}\}$  immediately dominating  $\{\{\text{paper}\}\}$ ; see also Gorn, 1967a: 215, ff.) is at 0 distance from any other expression with the same address.

Working with lexicalised neighbourhoods in WS has other advantages. Compare (24) with (27):

27) \*Which paper did John fall asleep while Mary reviewed ~~which paper~~?

---

<sup>22</sup> A more articulated structure for the *wh* operator is also possible (e.g., Cable 2008; Johnson 2016, 2020), where the operator and variable readings are divorced. Johnson's multidominance analysis, for instance, has a separate Q morpheme which dominates DP under CP, but the V that subcategorises for the DP does not dominate Q.

An analysis following the lines of Uriagereka (2002), Nunes (2004), or Franks (2014: 224) involves multiple workspaces and derivational cascades: in these frameworks, abstracting from certain differences, the opacity of adjuncts follows from (i) being derived in a separate workspace, and (ii) syntactic dependencies (probe-goal, filler-gap, etc.) operating with elements within a workspace/derivational cascade. In Uriagereka’s system, parallel derivational cascades are inserted in the main derivation ‘atomised’, already Spelled-Out, their internal structure being inaccessible for purposes of operations triggered at the main cascade (2012: 183)<sup>23</sup>. Even in a multidominance approach, however, additional restrictions must be put in place to prevent sideways movement from deriving (27) (as Franks 2014: 224-225 observes). Because the workspace is the Lexicon in our view (or, better put, because what we call the ‘Lexicon’ is the ground state of the workspace), there are no ‘multiple workspaces’ but only one, whose topological properties change (in contrast to Martin and Uriagereka’s view, it is not the topological properties of a phrase marker in the workspace that change, but of the workspace itself). Nothing in the definition of multidominance filters out (27) by itself, but working with lexicalised neighbourhoods and assuming the NDC delivers the desired results: there is no call for the address {which paper} in the neighbourhood of *fall asleep*, since the predicate only subcategorises for a subject:

28) Elementary graph 1:

$\langle e\langle T, \text{John} \rangle, e\langle T, \text{fall-asleep} \rangle, e\langle \text{fall-asleep}, \text{John} \rangle \rangle$

Elementary graph 2:

---

<sup>23</sup> Uriagereka (2002: 52-53), following Chomsky (1995), claims that the lack of superiority effects in (i) and (ii) is due to equidistance, which he deduces from the conditions on Multiple Spell Out:

- i) Which professor *t* saw which student?
- ii) Which student did which professor see *t*?

Since *which professor* is a complex phrase in a non-complement position, it must be derived in parallel, and thus *which professor* and *which student* (a complement) ‘do not compete within the same derivational space’. In the present framework, the ‘equidistance’ can be deduced from the simplified format of structural descriptions: *see* immediately dominates the root of the treelets corresponding to *which professor* and *which student*. While in Uriagereka’s system locality is enforced through LCA-linearisable command units, for us locality is enforced via lexicalisation *plus* the requirement that all dependencies be local to elementary graphs. In both (i) and (ii) there is a single anchor, thus a single elementary graph, and no inter-graph dependencies. Both subject and object are at the same level of embedding, immediately dominated by *see* (the order between them being determined by the sequentiality of Merge).

<*e*<while, T>, *e*<T, Mary>, *e*<T, review>, *e*<review, Mary>, *e*<review, which>, *e*<which, paper>>

With EG1 being the matrix structure, there is no structural position licensed for the filler: if, as in TAGs, we attempt to adjoin EG2 to EG1, we will not get *which paper* taking scope in the matrix structure, as it is not an argument or a modifier of the anchor of the matrix structure.

In the case of parasitic gaps, however, there is a call for the address {*which paper*} in all neighbourhoods involved (with the structurally highest one receiving an operator interpretation, possibly along the lines of Johnson 2016). Thus, in

29) Which paper did John file ~~which paper~~ after reviewing ~~which paper~~?

There are two neighbourhoods: one anchored by *file* and the other by *review*. Each of these contains a call for the (derived) address {*which paper*}<sup>24</sup>, which receives the same grammatical function (object) in both, being in the two cases first-Merged with the anchor. This address is at distance 0 from itself. In this context, the result of composition-as-graph union is similar to Martin and Uriagereka's (2014) approach, but its effects derive directly from the properties of the workspace as defined in **Section 2** and the addressing system. The core idea is that if we compose two (or more) graphs all of which contain an expression with the same address, the resulting structure will only contain one such expression, which enters dominance relations with expressions in each of the graphs.

#### 4.2.1 Deriving terseness in chain dependencies

Let us now look at some apparently simple cases:

- 30) a. John admires John
- b. John admires himself
- c. \*John admires (intended: 'John admires himself')
- d. \*Who<sub>*i*</sub> does John<sub>*i*</sub> admire?

---

<sup>24</sup> Under a structure sharing analysis of exhaustive obligatory control, {*John*} is also called in both elementary graphs (Krivochen, 2023b: §6.4).

The two *John*'s in (30a), with neutral intonation, do not refer to the same entity: they have distinct semantic value, and thus distinct addresses (say,  $\{\{\text{John McLaughlin}\}\}$  and  $\{\{\text{John Bonham}\}\}$ ). Thus, they would be 'repetitions': the concept of repetition refers only to the form of an expression, not its address or semantic value. In (30b), whether there is a copy or not would depend on the derivational origins of reflexives: if reflexives are derivational effects of having two co-indexed NPs in a local<sup>25</sup> environment (Gärtner 2014; Grohmann 2003; Hornstein 2001; Hornstein and Idsardi 2014; Lees and Klima 1963; McCawley 1970, among others), then a copy is needed, but no repetitions. (30c-d) show that additional constraints must hold: if *John* and *himself* are head and tail of a chain, how can we account for the fact that reflexive predicates require the Spell-Out of both calls to the same address but interrogatives do not?

In the present view, the definition of workspace must play a role in accounting for these facts. What matters in (30a) is that both instances of the word 'John' do not point to the same region in the workspace, as they have different semantic values. This is given, in that (30a) cannot be interpreted as (30b): we need to provide an adequate description of why this is the case. Under the assumption that the syntactic computation manipulates lexical tokens, it is indeed difficult to see how to differentiate between (30a) and (30b) without additional devices. However, if we consider our definition of neighbourhood, we can say something interesting on the matter. Recall that in our approach syntactic operations link points, creating graphs in a metricised space. The crucial fact about (30b) is that there is an indexed expression which establishes two distinct relations with the predicate *admire* (subject-of and object-of): we follow Reuland and Reinhart (1993: 662) in defining a predicate as reflexive if two of its arguments are coindexed. In our approach, this means having an expression which establishes two distinct grammatical relations with a predicate: derivationally, the predicate first-Merges and

---

<sup>25</sup> 'Local' means 'within the neighbourhood of a single lexical predicate'. Specifically, for this case, the neighbourhood of a transitive verb and which does not include a passive auxiliary.

second-Merges with the same basic expression. The irreducible graph thus generated would be  $G = \langle e \langle \text{admire}, \text{John} \rangle, e \langle \text{admire}, \text{John} \rangle \rangle$ , diagrammed in (31)<sup>26</sup>:

The definition of ‘reflexive anaphor’ in this context (recasting Reuland and Reinhart’s insight) is a nominal expression that corresponds to a node that is the tail of parallel arcs (which necessarily makes the anaphor and its ‘antecedent’ co-arguments): edges  $e_1$  and  $e_2$  are parallel iff  $e_1 \langle v_i, v_j \rangle \wedge e_2 \langle v_i, v_j \rangle$ . If we adopted a BPS-style diagram, the definition of *parallel arc* would need some reworking, since each call to the address  $\{\text{John}\}$  is immediately dominated by distinct segments of the same category<sup>27</sup>,  
<sup>28</sup>.

The analysis is different in the case of (30a): here, each *John* corresponds to a distinct indexed expression. The structural description of (30a) features no parallel arcs:

<sup>26</sup> The relation *parallel* is crucial to this analysis, as it allows an expression to be in two different grammatical relations with another. In Postal’s (2010: 18) terms,

‘one good reason to assume parallel arcs is that for certain types of grammatical relations a single phrase has the possibility of bearing more than one to the same larger constituent.’

<sup>27</sup> Alternatively, BPS-style trees could be read as analogous to TAG derivation trees (Frank 2006: 160; Sarkar and Joshi 1997: 610), keeping track of the order of introduction of arguments and adjuncts and the category of derived expressions resulting from these composition operations (with interesting consequences for the definition of grammatical functions, see Dowty 1982). In this case, however, BPS-style diagrams would be strictly analytical tools, rather than objects in the workspace. We leave this intriguing possibility aside in this paper.

<sup>28</sup> (32) can be converted into (31) (and (33b) below into (33a)) under a graph-theoretic interpretation of BPS via *edge contraction*, if we impose the condition that head and tail of an arc must be identically indexed to undergo contraction.

33)

Irreducible graph

BPS

The difference between (30a), which in Chomsky’s terms would involve ‘repetitions’ (of an exponent) and (30b), which would involve ‘copies’ is not something that the interfaces must invoke any special operations or principles to account for other than properties of the workspace: in one case there is one indexed expression that establishes more than one relation with a single predicate, in the other, there are two distinct nodes with two distinct addresses, which happen to share PF exponents<sup>29</sup>. Crucially, these exponents cannot be part of the addresses, nor of their content: the theory defended here requires late insertion of PF exponents.

In this context, a configurational definition of local reflexivity allows us to do two things: first, dispense with indexing and avoid the multiplication of nodes in structural descriptions. This is a feature that our analysis has, to greater or lesser extents, in common with that of Hornstein (2001: Chapter 5) -based on Movement-, Gärtner (2014) -implementing multidominance on a Phrase Linking Grammar (see also Peters and Ritchie 1981)-, Perlmutter (1980: 209) -using ‘multiattachment’ in Relational Grammar- and Grohmann (2003, 2013) -as a repair strategy for anti-locality violations-. Second, and differently from the aforementioned works, we can derive the distinct application of

---

<sup>29</sup> Collins and Groat (2018) consider a multidominance approach (specifically along the lines of Citko, 2011, which has some differences with respect to the framework explored here) to the distinction between copies and repetitions in Minimalism. Their critique of the multidominance approach begins as follows:

‘One issue that comes up right away is that [a multidominance tree] is a graph theoretic object. In minimalism, Merge forms sets {X, Y}’

The argument proceeds by rejecting a graph-theoretic approach and considering problems with a set like {John<sub>1</sub> {T, {be, {seen, John<sub>1</sub>}}}}, Collins & Groat correctly point out that the only way to make it work in Minimalism (where syntactic terminals are lexical tokens) is by introducing indices, thus violating the Inclusiveness Condition (see also Krivochev 2015b). The system proposed here does not require diacritics: either the two ‘John’s have the same addresses or they do not. Our system is based on the idea that the workspace contains graphs rather than sets, but even in a strict set-theoretic Minimalist approach the core issue seems to be defining how syntactic terminals are defined and what nodes in a phrase structure tree stand for (see also Gärtner 2022).

‘generalised terseness’ to reflexives and *wh*-dependencies from configurational differences. Let us see how.

Johnson (2020: 113) provides a definition of ‘terseness’ as a condition on chain Spell-Out (see also Grohmann’s 2003, 2013 *Condition on Domain Exclusivity*, which enforces terseness within local syntactic domains):

‘Terseness: When a term is moved from one position to another, it gets spoken in only one of those positions.’

There is no movement *stricto sensu* in our analysis of anaphoric dependencies, but Johnson’s condition can be generalised beyond movement chains:

Generalised terseness: When the address corresponding to a term is called from more than one syntactic context, it gets spoken in only one of those contexts.

We have a puzzle in our hands (as observed by a reviewer): if the same mechanism underlies both reflexives and *wh*-dependencies, one may ask why terseness only applies to one. In other words: why is (34a) grammatical but (34b) ungrammatical?

34) a. Who does John admire ~~who~~?

b. \*John admires ~~John~~ (intended: John admires himself)

The first thing to note is that despite the formal mechanism deriving both cases being the same (and in both cases we have a single elementary graph due to there being a single lexical anchor), the syntactic configuration is different: only (34b), in the intended reading, could contain parallel arcs. If parallel arcs were involved in (34a) (such that *who* and *John* were coindexed), the result would be a case of strong crossover (cf. (30d)), which is independently ruled out. (34a) and (34b) have distinct structures (35a-b) respectively:

35) a.  $G = \langle e\langle C, who \rangle, e\langle C, T \rangle, e\langle T, John \rangle, e\langle T, admire \rangle, e\langle admire, John \rangle, e\langle admire, who \rangle \rangle$

b.  $G = \langle e \langle T, \text{John} \rangle, e \langle T, \text{admire} \rangle, e \langle \text{admire}, \text{John} \rangle, e \langle \text{admire}, \text{John} \rangle \rangle$

There is a configurational difference between (34a) and (34b) that disappears under traditional Merge.

As for why generalised terseness applies to only one of these configurations (or, rather, why it cannot apply to (34b)), our proposal is that the answer lies in what Grohmann (2003: 78, 2013) calls ‘drastic effects on the output’: a realisation of a syntactic object SO at PF. In our case, the ‘drastic effect’ is the assignment of a reflexive morphophonological exponent, triggered by the assignment of two different grammatical functions to the same expression within an elementary graph, since this relation counts as ‘too local’ (in the same way that movement within a Prolific Domain does). The core idea is that the assignment of two distinct grammatical functions to the same addressed expression  $\{\text{John}\}$  within an elementary graph licenses a violation of generalised terseness in the same way that Grohmann’s (2003, 2013) Copy Spell Out does, but -emphatically- without movement or indeed copies<sup>30</sup>. The situation is different in *wh*-extractions: there is only one primary grammatical function involved (object, in (35a)), and conditions for these ‘drastic effects’ to arise do not hold. Thus, we expect resumption in *wh*-interrogatives to be banned in these contexts:

36) a. \*Who<sub>i</sub> does John admire him<sub>i</sub>?

b. \*Who<sub>i</sub> he<sub>i</sub> admires John?

This analysis correctly excludes the possibility of Spelling-Out copies left by A-movement in the standard cases: in passivisation, there is only one grammatical function assigned to the raised

---

<sup>30</sup> Copy Spell-Out is a mechanism whereby the lower copy of a syntactic object created via movement within a local domain can be Spelled-Out as a distinct minimally feature-matching exponent. In Grohmann’s (2003, 2013) system, Copy Spell-Out is a repair strategy for violations to his Condition on Domain Exclusivity, which bans multiple occurrences of an SO within a local syntactic domain (‘An object O in a phrase marker must have an exclusive Address Identification AI per Prolific Domain  $\Pi\Delta$ , unless duplicity yields a drastic effect on the output’; 2003: 78). A semi-formal formulation of Copy Spell Out is as follows (from Grohmann 2013):

‘Copy Spell-Out (PF-driven viz. the CDE [Condition on Domain Exclusivity])  
Structural Description: Given copies  $C_1$  and  $C_2$ , where  $C_1$  LCA-precedes  $C_2$ , and  
 $C_1$  and  $C_2$  are in the same Prolific Domain.  
Structural Change: Spellout-as-Modified  $C_2$ ’

The basic idea is clear: syntactic dependencies are local, but cannot be *too* local. The major difference between Grohmann’s view and ours is that there is no movement in the derivation of reflexives (and thus no copies).

syntactic object; in raising there is more than one elementary graph involved (Frank 2002: Chapter 3) such that the raised term (which is structure-shared; see Pollard and Sag 1994: 136; Börjars et al. 2019: 102, ff.) gets assigned a single grammatical function in each: either subject upstairs and downstairs (with verbs such as *seem*) or object upstairs and subject downstairs (with verbs such as *expect*). This approach entails that the conditions for the assignment of PF exponents to syntactic terminals are checked at the level of elementary graphs, as is semantic interpretation (along the lines of Jacobson’s 2012 direct compositionality Type 3). As such, while in our theory non-monotonicity does not require the multiplication of workspaces (compare with Uriagereka, 2002; Nunes, 2004), locality is nonetheless enforced, via lexicalised neighbourhoods<sup>31</sup>.

The identification of identical addresses in distinct contexts follows from the characterisation of the workspace in **Section 3**, and proves particularly useful to address the problem of distinguishing between *copies* and *repetitions*. The terms ‘occurrence’, ‘copies’, ‘repetitions’ have been used in Minimalist syntax to argue for or against specific forms of structure building (Collins and Groat 2018; Chomsky 2019, 2021); in all cases their problematic nature is widely acknowledged. Many of the problems identified in the literature arise because derivations operate over sets of tokens lexical items and sets of sets of tokens of lexical items. For example, Chomsky (2013: 40) uses ‘copies’ and ‘repetitions’ as types of occurrences. Chomsky (2000: 115) says that “an occurrence of  $\alpha$  in  $K$  to be the full context of  $\alpha$  in  $K$ ”, where  $K$  is a syntactic object. Presumably, ‘context’ here refers to the mother-daughters of  $\alpha$ , in a PS tree, but set-theoretically we should refer exclusively to relations of membership and co-membership. Once we do, however, we need either indexing to keep track of occurrences, or allow for multisets to have strict identity between copies (despite changes in their featural makeup). Both options present, as has been pointed out in the literature, additional problems.

At the core of the problem of distinguishing copies and repetitions there is a confusion, we think, between phrase markers as sets, phrase markers as graphs, and diagrams of phrase markers (see

---

<sup>31</sup> Linguistic variation would arise when considering (i) ‘Which language makes available which grammatical formative in which structures?’ (Grohmann 2013) and (ii) the size of elementary graphs, including the empirical issue of determining what counts as a lexical predicate in different languages (Krivochen and Padovan 2021).

McCawley 1998: 47-48; Postal 2010: 7, ff. for discussion). Making explicit the mechanisms of each is necessary to properly compare the empirical adequacy of set theoretic and graph theoretic syntax.

Because we are dealing with two or more calls to the same location in WS, we can capture the idea of *copies* without multiplying nodes or extending WS: this multiplication is unavoidable in set-theory based syntax but avoided in graph-theoretic syntax. When neighbourhoods are combined (at the root or non-root), identical addresses in distinct neighbourhoods are treated as a single syntactic object, as addresses are instructions to retrieve an interpretation (or access a portion of the lexical space; see Manzini and Savoia 2011: Introduction for related discussion) and structure composition is graph union.

## 5. Conclusions

Let us take stock. Our starting point was the contrast between the lack of attention to the formal properties of *workspace* in Minimalist syntax and its centrality for operations of structure building and mapping. Because the properties of workspaces are often left undefined, it is hard to link properties of objects or operations to properties of the workspace. In this context, we needed to determine what we want the theory of workspaces to do for us:

- Appealing to workspaces must make the definition of syntactic relations more transparent or explicit, it must capture some property of grammatical entities that would be otherwise overlooked or mischaracterised.
- We want to capture the fact that points in a space can be close or far apart to different degrees: we can call the function that defines just how close or far apart points are the *metric* of the space.
- We want to preserve distinguishability: two distinct points A and B in a space X can be arbitrarily near or far apart, but never have 0 distance. A and B can have 0 distance in X iff  $A = B$ .

- We want to be able to define the neighbourhood of a point in the space, and determine whether that neighbourhood is accessible to other points in the space or not. This results in a workspace-based theory of local relations.

We proposed a topological definition of workspace, and related its properties to the kinds of operations that apply and relations that can hold in that space. We built on previous work on dynamical frustration at the core of language to argue that the initial (pre-syntactic) state of the workspace is ultrametric: points in that space are basic expressions of the language indexed by a set of uniquely identifying addresses. Syntactic operations create neighbourhoods for lexical predicates (which enforce their subcategorisation frames) and create intersections between these neighbourhoods. In connecting expressions, syntactic operations modify the topology of the workspace, delivering a set of directed graphs in metric space, where internal and boundary sets can be defined. The metric space which results from the composition of local neighbourhoods delivers topological distinguishability as well as variable distances between points (Willard 2004; Munkres 2000). Structure sharing is enforced by the *identity property* of metric spaces and the addressing system. Locality is enforced by lexicalisation (not by topology), given the Elementary TAG Hypothesis: all syntactic dependencies must be established at the level of elementary graphs<sup>32</sup>.

Architecturally, IM and EM are unified as a single operation:  $\text{Merge}(X, Y) = e\langle X, Y \rangle$ . Graph-theoretic Merge satisfies MINIMAL YIELD (no new elements are created), BINARITY (as arcs only connect a head and a tail), and STABILITY (via unique indexing and multidominance). Furthermore, the workspace is never expanded. Under graph-theoretic Merge, IM and EM only differ in terms of the configurations that are created and their relation to argument structure (such that subcategorisation properties of anchors of elementary graphs are always satisfied by EM).

The empirical component of this paper pertains to the analysis of simple cases of copies vs. repetitions that have been raised in the literature. Conceiving of syntactic terms in structural descriptions as addresses allows us to dispense with the multiplication of nodes in dependencies

---

<sup>32</sup> In Krivochen (2023a) we propose that Minimal Search is also elementary-graph bound.

involving *copies* in favour of multiple calls for the same address, all of which are at 0 distance from each other following the identity property. It becomes possible to define structural descriptions that avoid set-membership paradoxes and simplify the system by dispensing with independent indexing mechanisms: this offers promising perspectives in the analysis of locality, long-distance dependencies, and co-reference. The relation between copies and theta-theory (highlighted in Chomsky, 2020a: 44, 2021: 21, ff.) follows if Merge satisfies selectional requirements of predicates: in Chomsky's (2021: 21) words, '*Merge must satisfy LSC [Language Specific Conditions], including  $\Theta$ -Theory*'. In the present framework, it does so by defining lexicalised neighbourhoods, where a lexical predicate immediately dominates the arguments it theta-marks.

We eliminate the distinction between a lexical space and a syntactic space: there is only *one* workspace, derivationally metricised, where strictly ordered directed graphs are constructed.
